

CS 343: Artificial Intelligence

CSPs II + Local Search

Prof. Yuke Zhu

The University of Texas at Austin

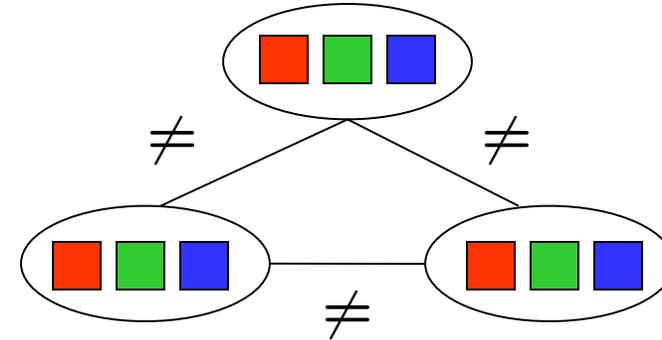

Announcements

- Homework 1 & Reading: Adversarial Search, Utilities
 - Due Yesterday 2/7
- Project 1: Search
 - Reminder: Due Wednesday 2/9 at 11:59 pm
- Homework 2: CSPs
 - Due Monday 2/23, at 11:59 pm.
 - Multiple resubmissions allowed.

Last time: CSPs

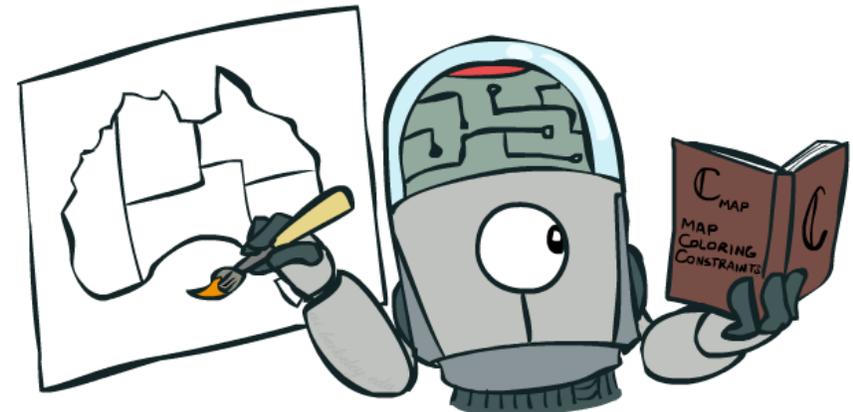

- CSPs:

- Variables
- Domains
- Constraints
 - Implicit (provide code to compute)
 - Explicit (provide a list of the legal tuples)
 - Unary / Binary / N-ary

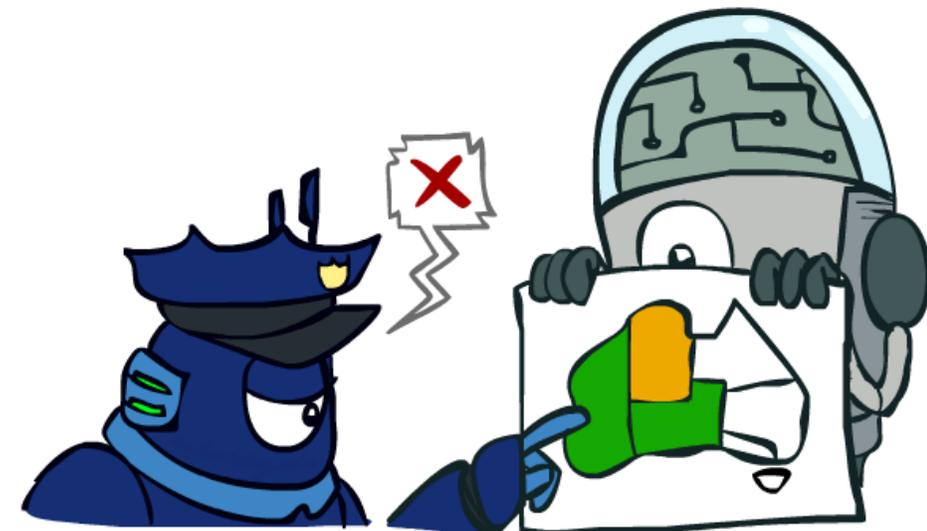

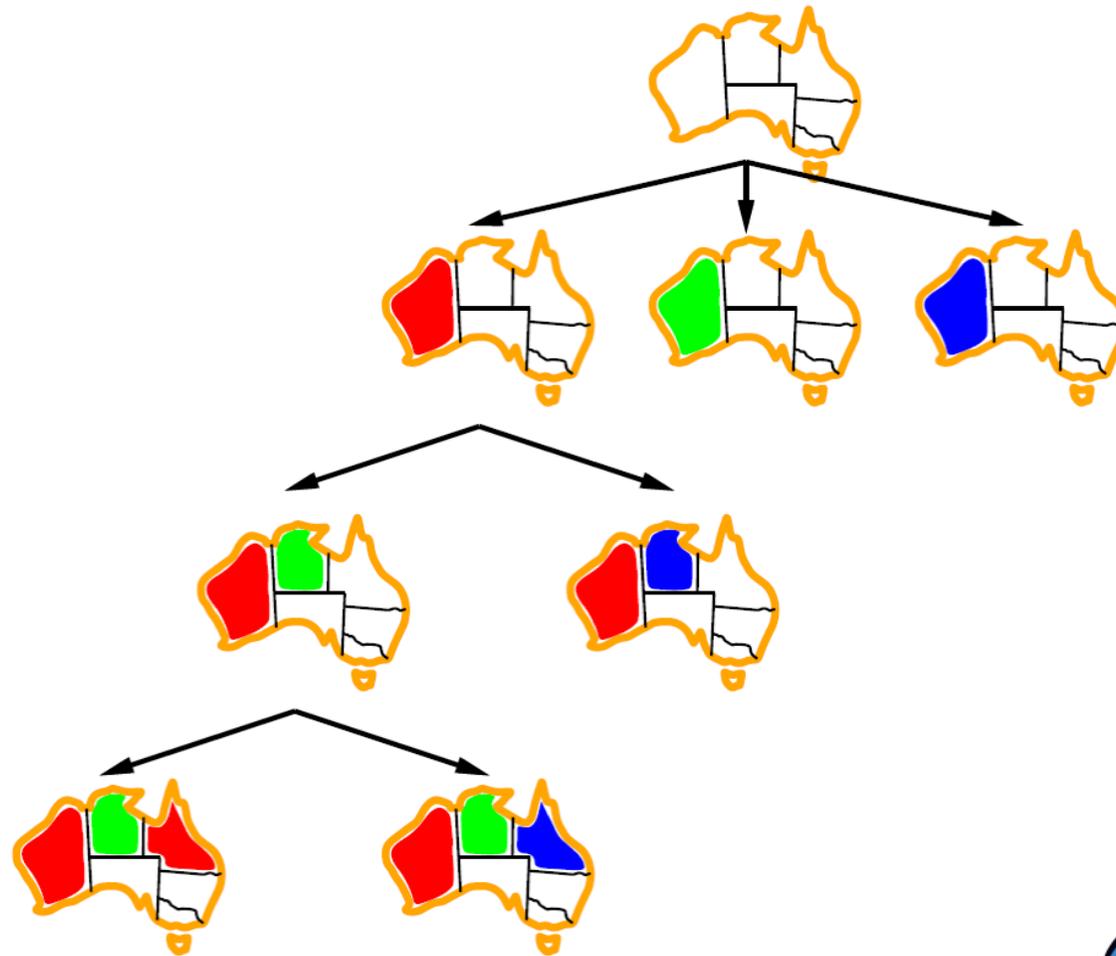

- Goals:

- Here: find any solution
- Also: find all, find best, etc.

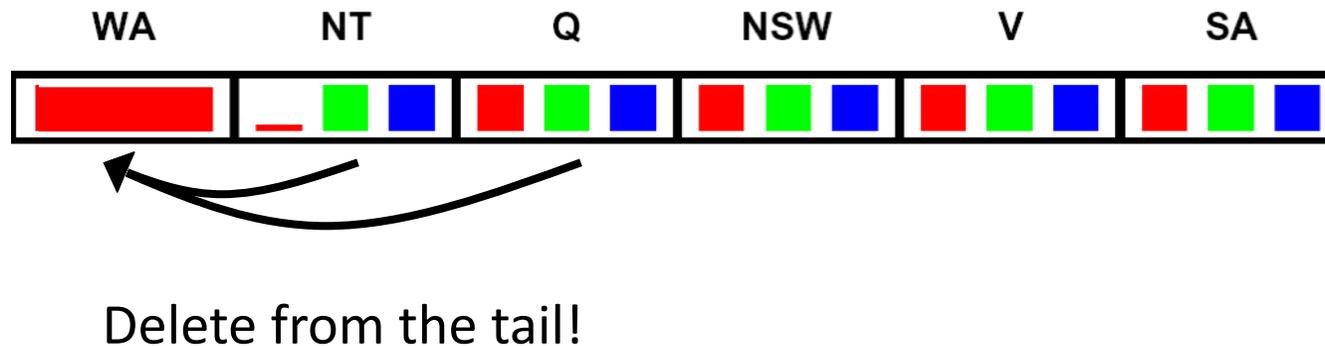

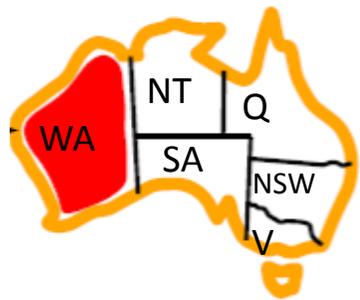

Last time: Backtracking

Last time: Consistency of A Single Arc

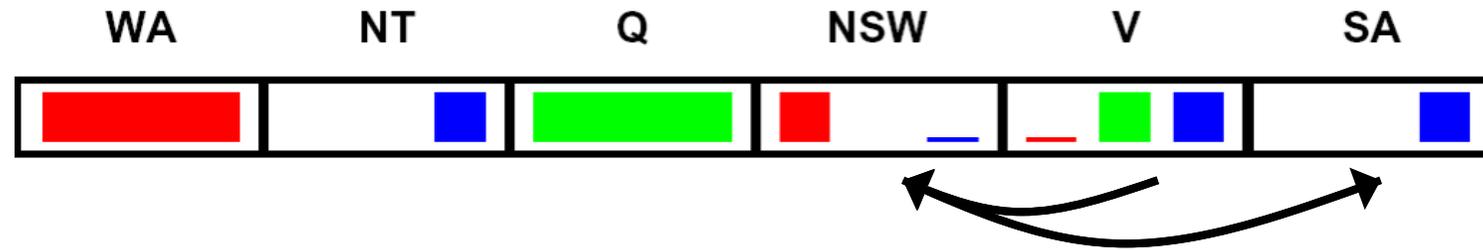

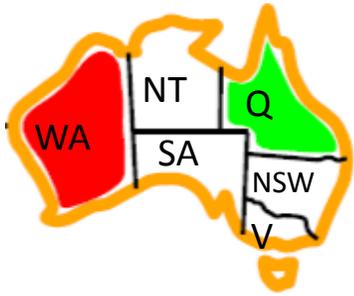

- An arc $X \rightarrow Y$ is **consistent** iff for *every* x in the tail there is *some* y in the head which could be assigned without violating a constraint

- Forward checking: Enforcing consistency of arcs pointing to each new assignment

Last time: Arc Consistency of an Entire CSP

- A simple form of propagation makes sure **all** arcs are consistent:

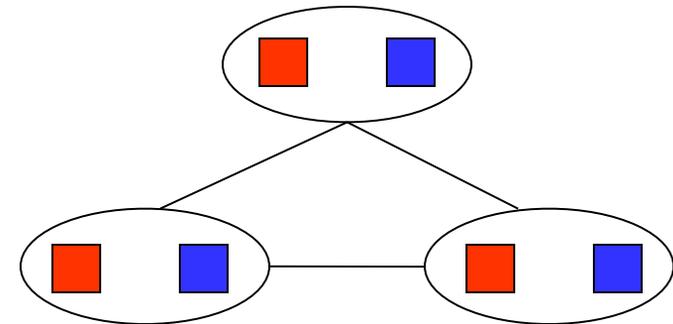

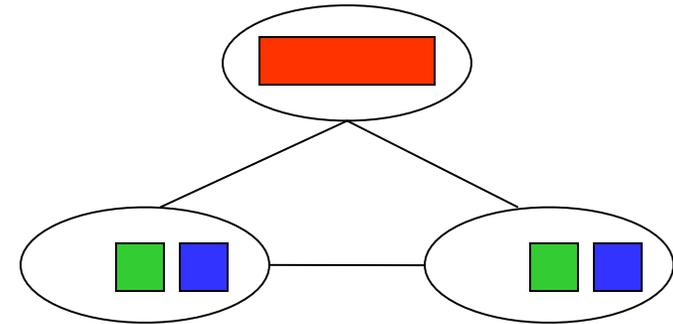

- Important: If X loses a value, neighbors of X need to be rechecked!
- Arc consistency detects failure earlier than forward checking
- Can be run as a preprocessor or after each assignment
- What's the downside of enforcing arc consistency?

Remember: Delete from the tail!

Limitations of Arc Consistency

- After enforcing arc consistency:
 - Can have one solution left
 - Can have multiple solutions left
 - Can have no solutions left (and not know it)
- Arc consistency still runs inside a backtracking search!

What went wrong here?

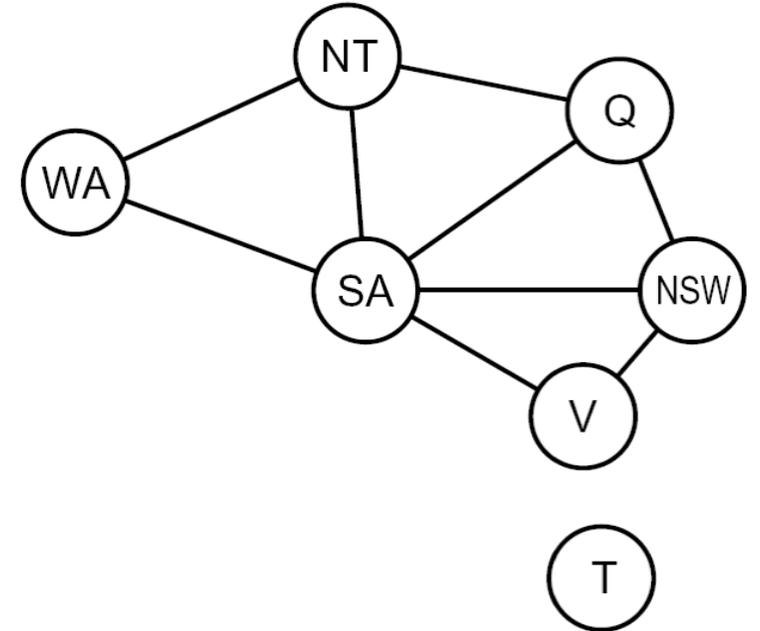

Improving Backtracking

- General-purpose ideas give huge gains in speed
 - ... but it's all still NP-hard
- Filtering: Can we detect inevitable failure early?
- Ordering:
 - Which variable should be assigned next? (MRV)
 - In what order should its values be tried? (LCV)
- Structure: Can we exploit the problem structure?

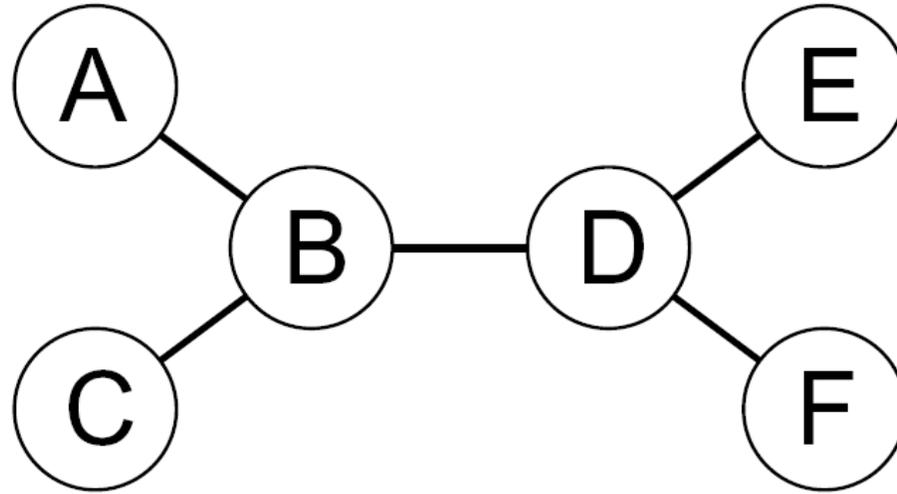

Problem Structure

- Extreme case: independent subproblems
 - Example: Tasmania and mainland do not interact
- Independent subproblems are identifiable as connected components of constraint graph
- Suppose a graph of n variables can be broken into subproblems of only c variables:
 - Worst-case solution cost is $O((n/c)(d^c))$, linear in n
 - E.g., $n = 80$, $d = 2$, $c = 20$
 - $2^{80} = 4$ billion years at 10 million nodes/sec
 - $(4)(2^{20}) = 0.4$ seconds at 10 million nodes/sec

Tree-Structured CSPs

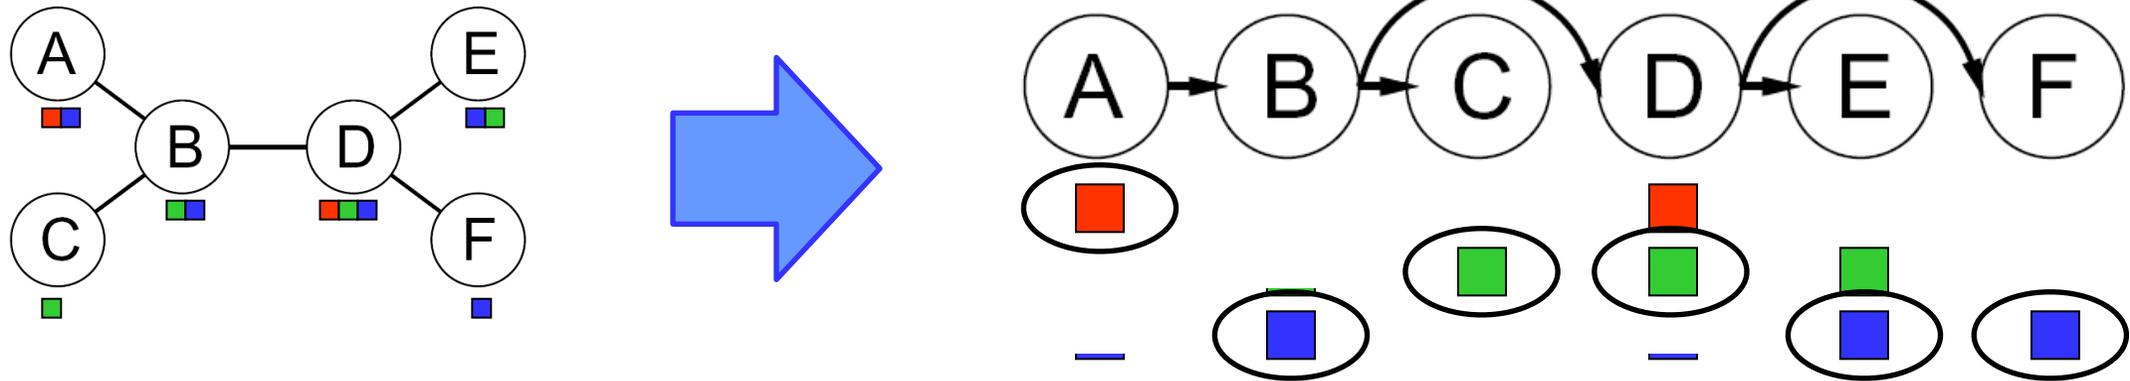

- Theorem: if the constraint graph has no loops, the CSP can be solved in $O(n d^2)$ time
 - Compare to general CSPs, where worst-case time is $O(d^n)$
- This property also applies to probabilistic reasoning (later): an example of the relation between syntactic restrictions and the complexity of reasoning

Tree-Structured CSPs

- Algorithm for tree-structured CSPs:

- Order: Choose a root variable, order variables so that parents precede children

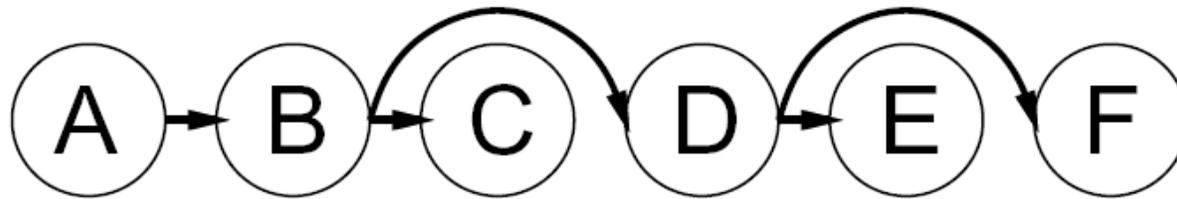

- Remove backward: For $i = n : 2$, apply $\text{RemoveInconsistent}(\text{Parent}(X_i), X_i)$
- Assign forward: For $i = 1 : n$, assign X_i consistently with $\text{Parent}(X_i)$

- Runtime: $O(n d^2)$ (why?)

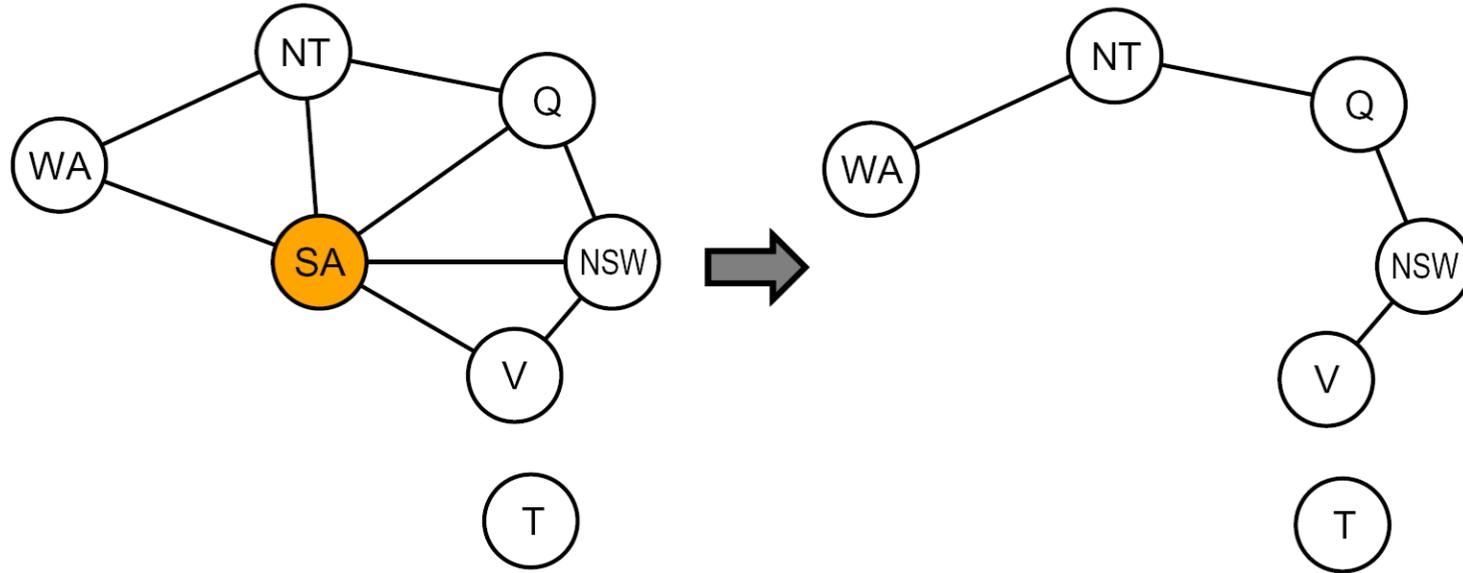

Tree-Structured CSPs

- Claim 1: After backward pass, all root-to-leaf arcs are consistent
- Proof: Each $X \rightarrow Y$ was made consistent at one point and Y 's domain could not have been reduced thereafter (because Y 's children were processed before Y)

- Claim 2: If root-to-leaf arcs are consistent, forward assignment will not backtrack
- Proof: Induction on position
- Why doesn't this algorithm work with cycles in the constraint graph?
- Note: we'll see this basic idea again with Bayes' nets

Nearly Tree-Structured CSPs

- Conditioning: instantiate a variable, prune its neighbors' domains
- Cutset conditioning: instantiate (in all ways) a set of variables such that the remaining constraint graph is a tree
- Cutset size c gives runtime $O(d^c (n-c) d^2)$, very fast for small c

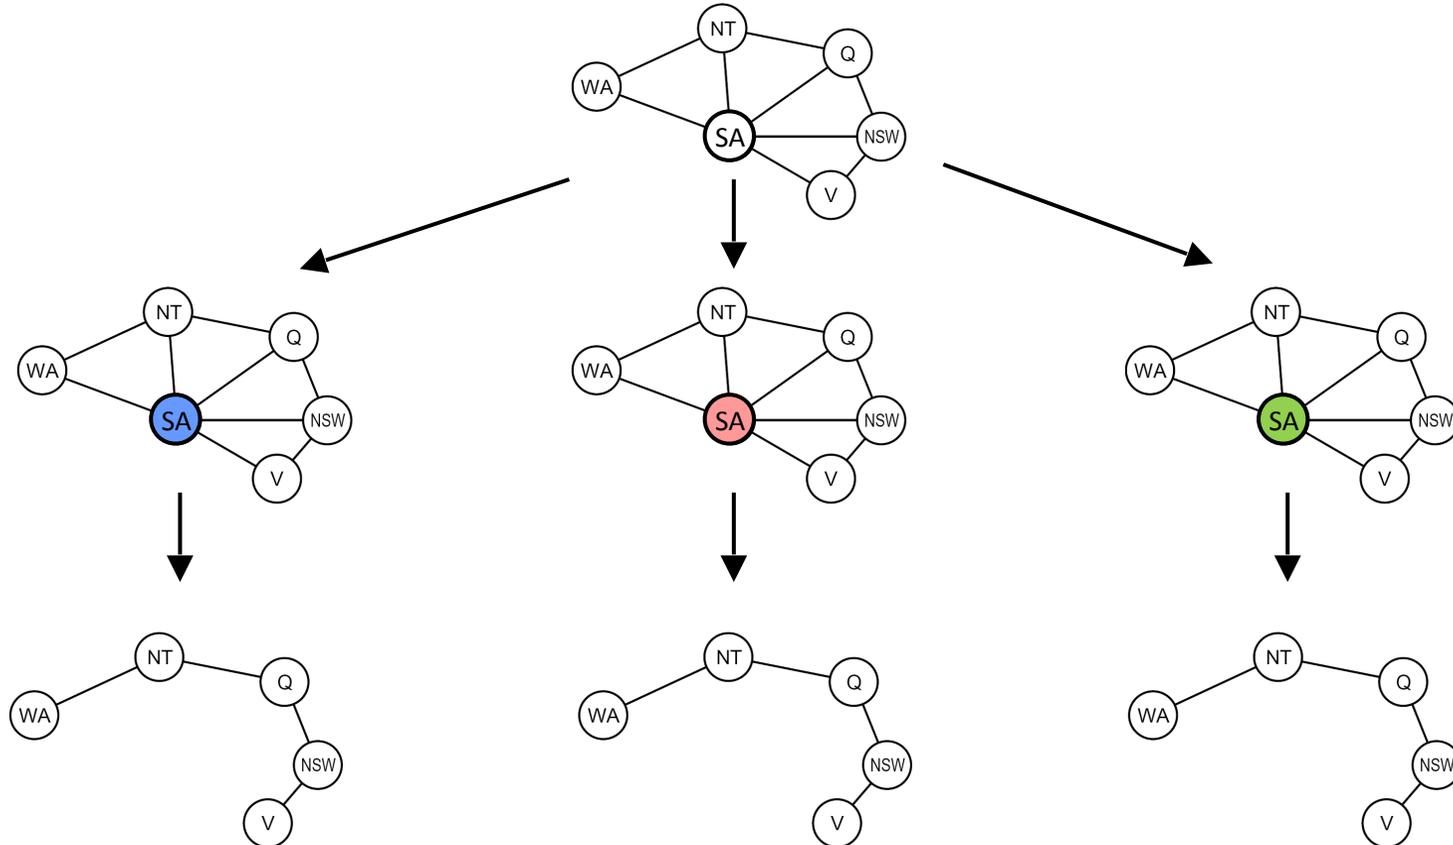

Cutset Conditioning

Choose a cutset

Instantiate the cutset
(all possible ways)

Compute residual CSP for
each assignment

Solve the residual CSPs
(tree structured), removing any
inconsistent domain values w.r.t.
cutset assignment

d^c

$(n-c)d^2$

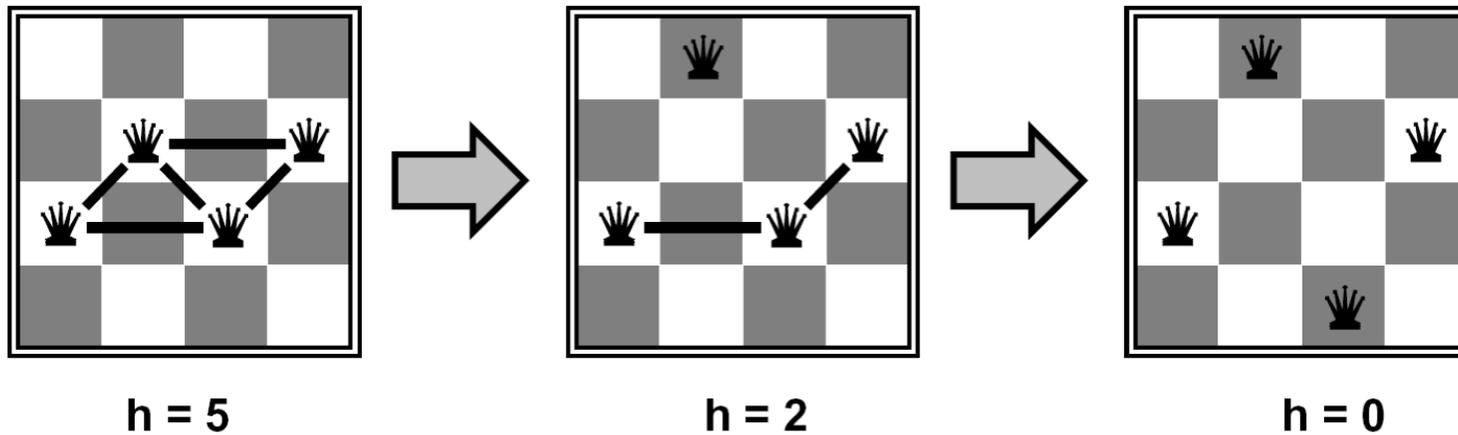

Exercise: Cutset Exercise

Iterative Algorithms for CSPs

- Local search methods typically work with “complete” states, i.e., all variables assigned
- To apply to CSPs:
 - Take an assignment with unsatisfied constraints
 - Operators *reassign* variable values
 - No fringe! Live on the edge.
- Algorithm: While not solved,
 - Variable selection: randomly select any conflicted variable
 - Value selection: min-conflicts heuristic:
 - Choose a value that violates the fewest constraints
 - I.e., hill climb with $h(n)$ = total number of violated constraints
- Can get stuck in local minima (we’ll come back to this idea in a few slides)

Example: 4-Queens

- States: 4 queens in 4 columns ($4^4 = 256$ states)
- Operators: move queen in column
- Goal test: no attacks
- Evaluation: $c(n) =$ number of attacks

Video of Demo Iterative Improvement – n Queens

74 N-Queens Iterative Improvement Demo

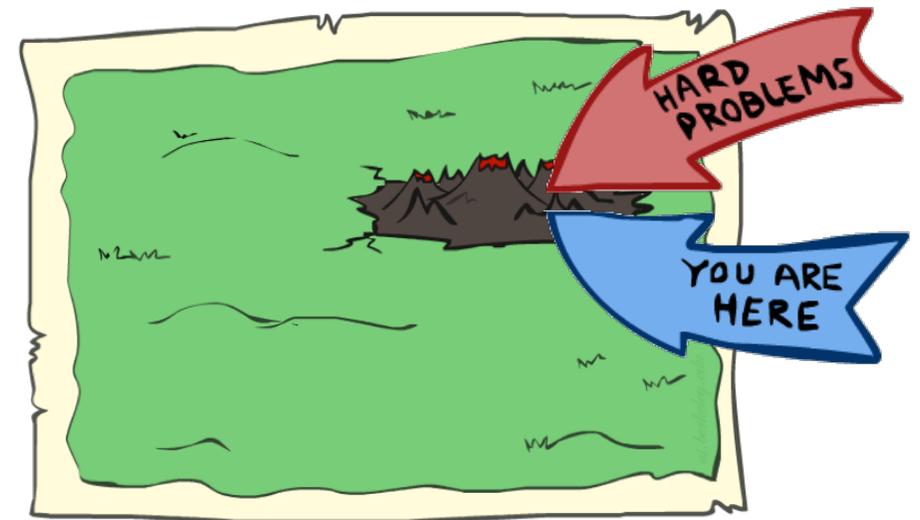

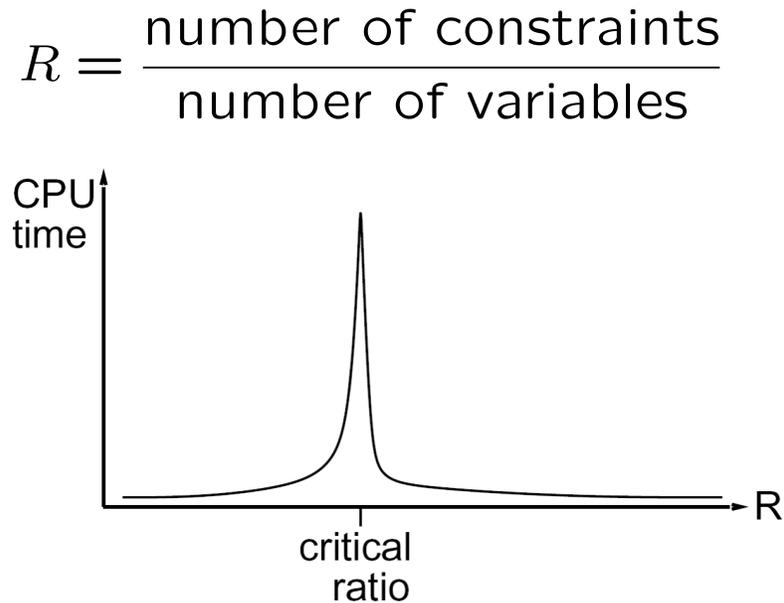

| | | | | |
|---|---|---|---|---|
| 4 | | | | |
| 4 | 2 | 1 | 1 | 0 |
| 4 | | | | |
| 4 | | | | |
| 4 | | | | |

In
Pieces can only move to a new column in their fixed row. Numbers
show number of threats to a position.

Performance of Min-Conflicts

- Runtime of min-conflicts is on n-queens is **roughly independent of problem size!**
 - Why?? Solutions are densely distributed in state space
- Given random initial state, can solve n-queens in almost constant time for arbitrary n with high probability (e.g., n = 10,000,000) in ~50 steps!
- The same appears to be true for any randomly-generated CSP *except* in a narrow range of the ratio

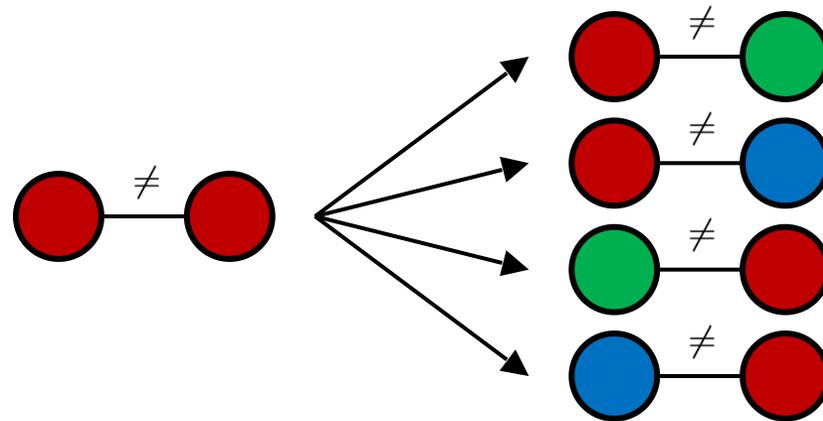

Summary: CSPs

- CSPs are a special kind of search problem:
 - States are partial assignments
 - Goal test defined by constraints
- Basic solution: backtracking search
- Speed-ups:
 - Ordering
 - Filtering
 - Structure
- Iterative min-conflicts is often effective in practice

Local Search

- Tree search keeps unexplored alternatives on the fringe (ensures completeness)
- Local search: improve a single option until you can't make it better (no fringe!)
- New successor function: local changes

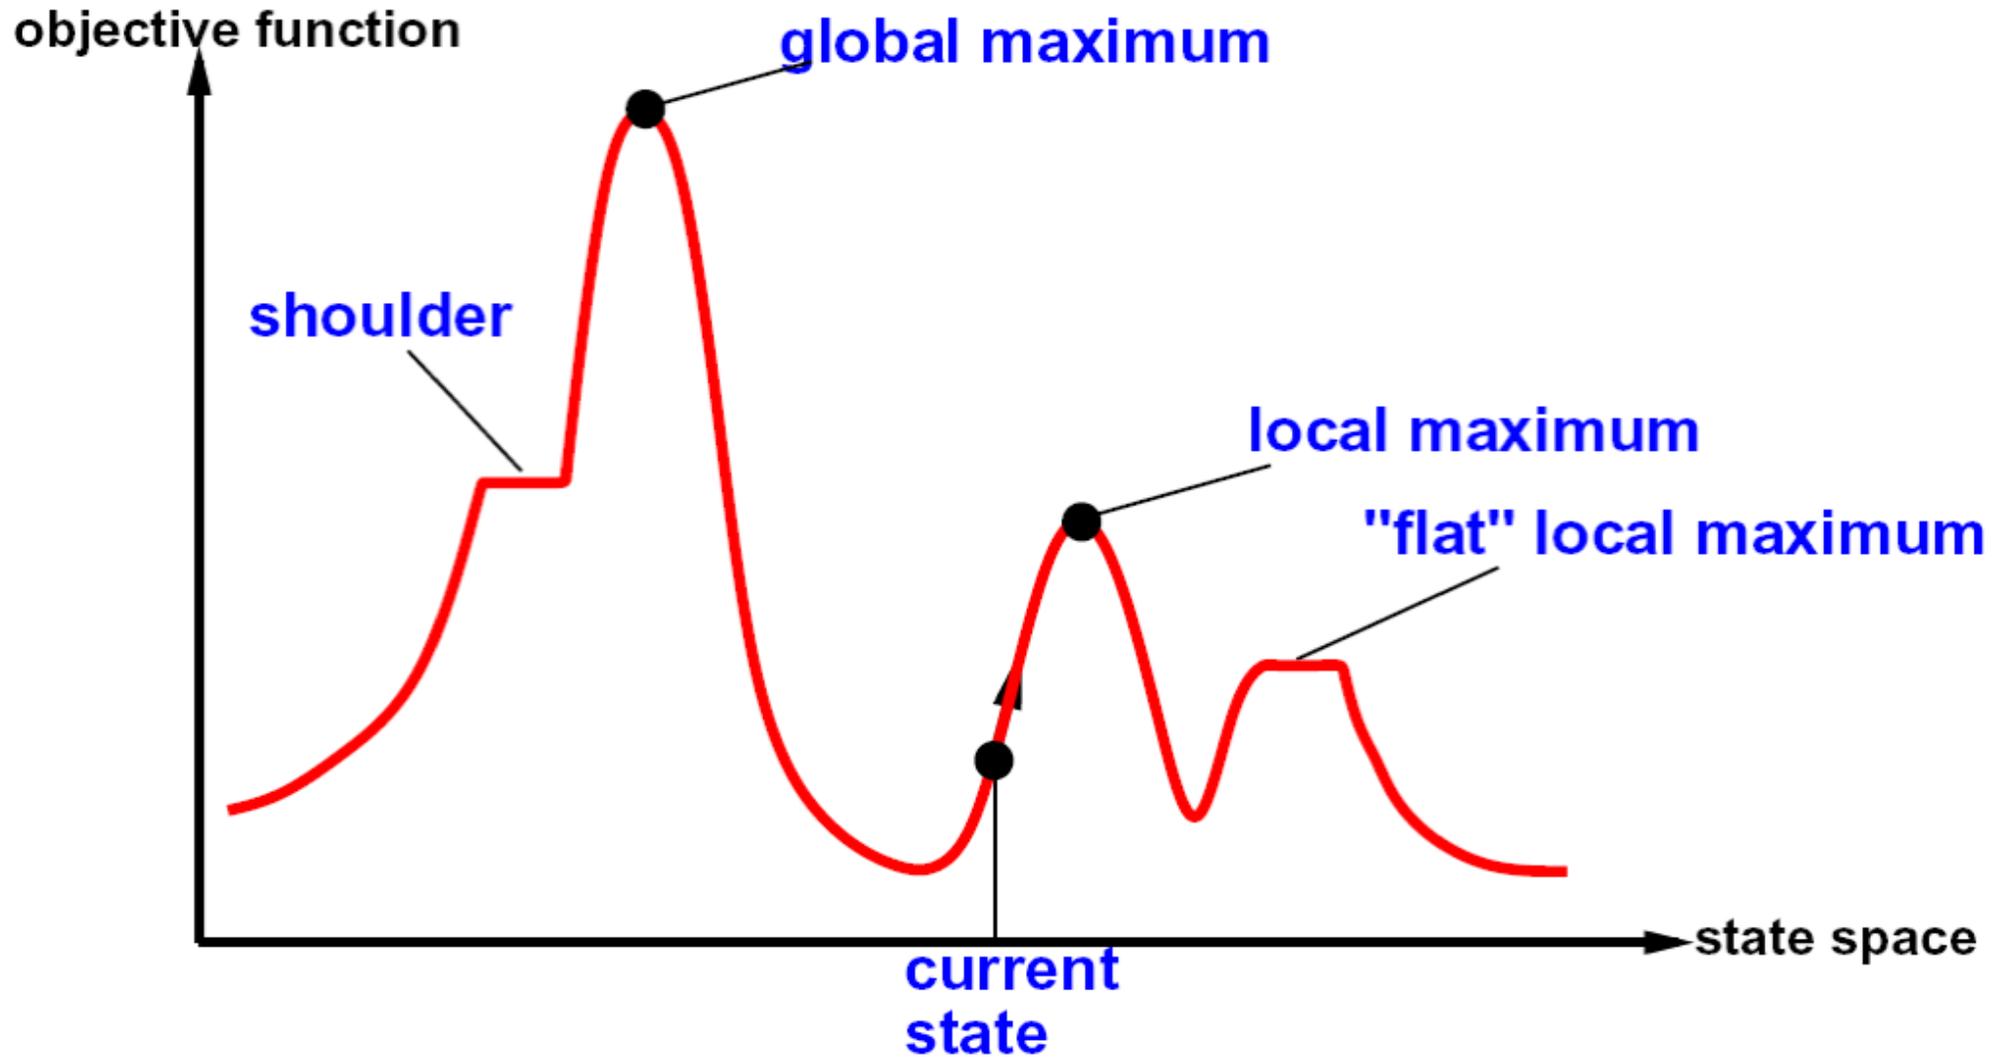

- Generally much faster and more memory efficient (but incomplete and suboptimal)

Hill Climbing

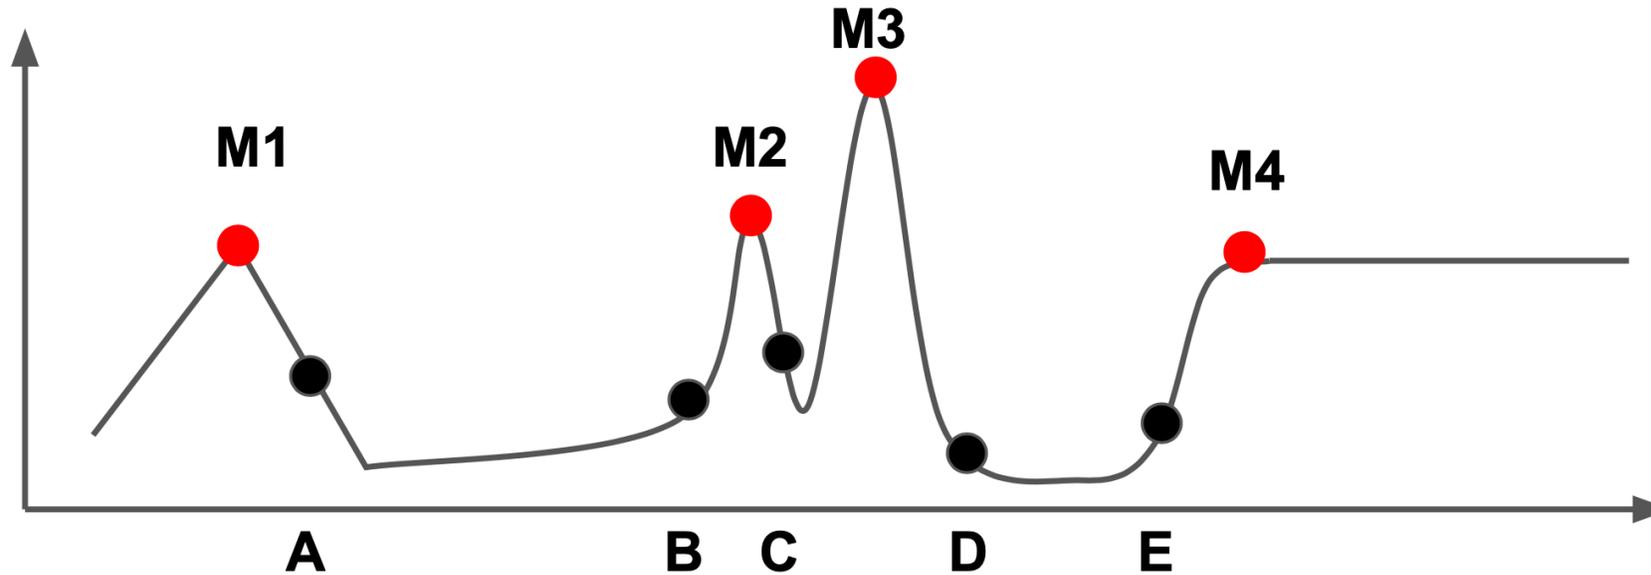

- Simple, general idea:
 - Start wherever
 - Repeat: move to the best neighboring state
 - If no neighbors better than current, quit
- What's bad about this approach?
 - Complete?
 - Optimal?
- What's good about it?

Hill Climbing Diagram

Hill Climbing Exercise

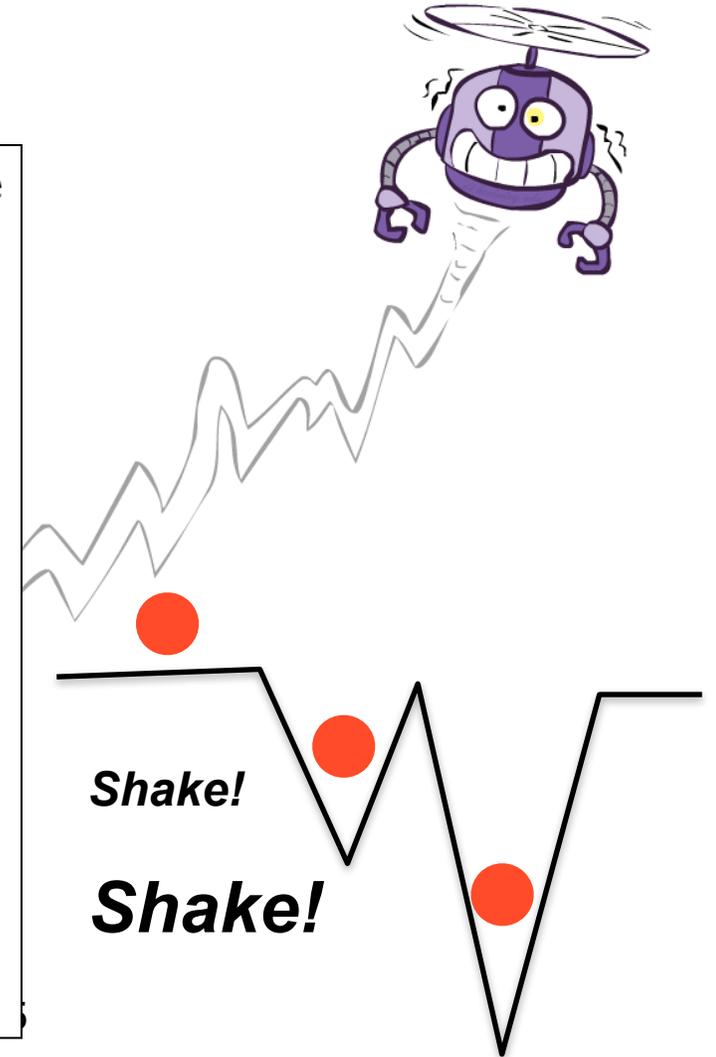

Simulated Annealing

- Idea: Escape local maxima by allowing downhill moves
 - But make them rarer as time goes on

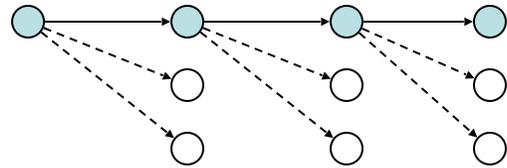

```
function SIMULATED-ANNEALING(problem, schedule) returns a solution state
  inputs: problem, a problem
           schedule, a mapping from time to "temperature"
  local variables: current, a node
                   next, a node
                   T, a "temperature" controlling prob. of downward steps

  current ← MAKE-NODE(INITIAL-STATE[problem])
  for t ← 1 to ∞ do
    T ← schedule[t]
    if T = 0 then return current
    next ← a randomly selected successor of current
     $\Delta E$  ← VALUE[next] - VALUE[current]
    if  $\Delta E > 0$  then current ← next
    else current ← next only with probability  $e^{-\Delta E/T}$ 
```

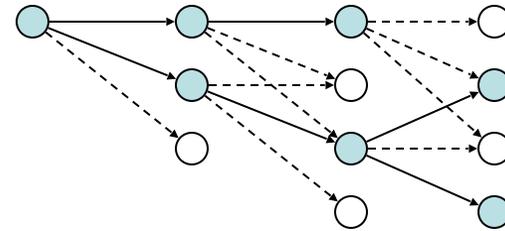

Beam Search

- Like greedy hillclimbing search, but keep K states at all times:

Greedy Search

Beam Search

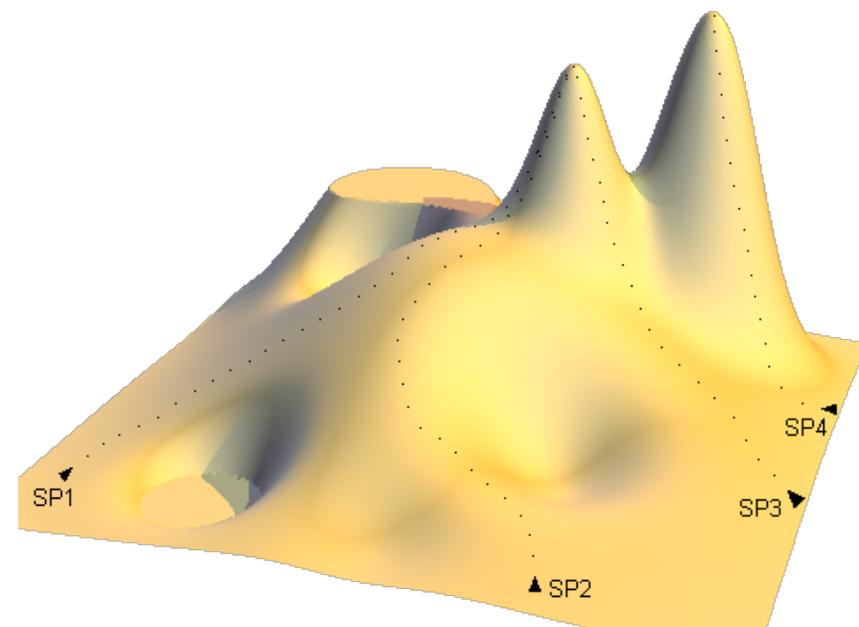

- Variables: beam size, encourage diversity?
- The best choice in MANY practical settings
- Complete? Optimal?
- Why do we still need optimal methods?

Gradient Methods

- Continuous state spaces
 - Problem! Cannot select optimal successor
- Discretization or random sampling
 - Choose from a finite number of choices
- Continuous optimization: Gradient ascent
 - Take a step along the gradient (vector of partial derivatives)
- What if you can't compute gradient?
 - i.e. maybe you can only sample the function
 - Estimate gradient from samples!
 - “Stochastic gradient descent”
 - We will return to this in neural networks / deep learning

$$\nabla f = \left(\frac{\partial f}{\partial x_1}, \frac{\partial f}{\partial y_1}, \frac{\partial f}{\partial x_2}, \frac{\partial f}{\partial y_2}, \frac{\partial f}{\partial x_3}, \frac{\partial f}{\partial y_3} \right)$$

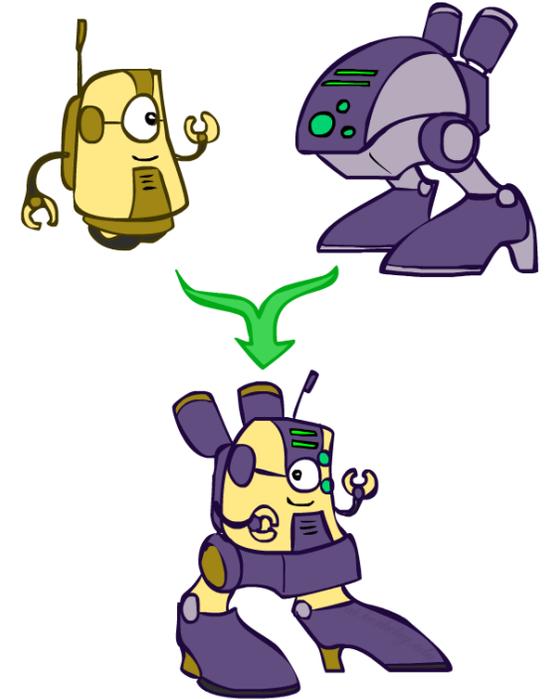

$$x \leftarrow x + \alpha \nabla f(x)$$

Genetic Algorithms

Fitness

- Genetic algorithms use a natural selection metaphor
 - Keep best N hypotheses at each step (selection) based on a fitness function
 - Also have pairwise crossover operators, with optional mutation to give variety
- Possibly the most misunderstood, misapplied (and even maligned) technique around

Example: N-Queens

- Why does crossover make sense here?
- When wouldn't it make sense?
- What would mutation be?
- What would a good fitness function be?

Next Time: Adversarial Search!
